

RF-MAP-00 Explanation

How to Think About RF5 Inheritance Success

How to Think About RF5 Inheritance Success

Purpose of This Map

This map is an introductory diagram explaining the Candidate Count Model, the most important organizing idea in this RF5 inheritance research.

In RF5 equipment inheritance, many players ask, “Why is this not succeeding?” or “Why does the success rate change even with the same setup?” In practice, however, inheritance success is strongly affected first by the Candidate Count, rather than simply by the strength or type of each individual effect. This map organizes that idea so it can be understood at a glance.

What Is Candidate Count N?

Candidate Count N is the total number of candidates subject to selection. This research treats Candidate Count N as a central concept in inheritance processing.

When the Candidate Count is small, the probability that a desired effect will be selected is higher. Conversely, as the Candidate Count increases, competition among candidates increases and the probability that the desired effect will be selected decreases.

Candidate Count Model

The Candidate Count Model is the central organizing idea of this research. It provides a common basis for explaining phenomena such as Recursive Processing, Performance-Source Contamination, Auto Arrange, and Messhilite Inheritance.

Inheritance success is strongly governed first by Candidate Count N, rather than solely by the contents of the candidates themselves. As Candidate Count increases, competition increases and the probability of selecting the desired effect decreases. Conversely, limiting the Candidate Count improves the success probability. Many tests in this research were conducted to examine the validity of this model.

Factors That Increase Candidate Count

The left side of the map shows representative factors that increase Candidate Count.

Recursive Processing

Referencing internal arrangement information or inheritance information may generate additional candidates.

Performance-Source Contamination

Candidates derived from the source equipment are treated as candidates again, increasing Candidate Count. The Japanese source uses several older labels for the same observed phenomenon; this English edition standardizes the term as **Performance-Source Contamination** under the terminology authority established in Chapter 01.

Auto Arrange

When the required-material count is insufficient, an internal completion process may add candidates that are not visible to the player. This phrasing follows the RF-MAP-00 source; its relationship to Chapter 01's more specific condition is recorded in the Translation Report rather than silently repaired here.

Messhilite Inheritance

This is a special domain in which Candidate Count increase, order randomization, and position-dependent interference may occur together. In this research, it is an important observation target for examining the Candidate Count Model.

Impact on Success

When Candidate Count increases, the desired-candidate selection rate decreases. Practical burdens may therefore include:

- lower success probability;
- more required attempts;
- more reloads; and
- greater material consumption.

This research organizes these outcomes not merely as bad luck, but as results associated with changes in Candidate Count.

Position of This Map

RF-MAP-00 is an introductory diagram showing the most basic idea in RF5 inheritance research. RF-MAP-01 surveys the structure of the research as a whole, whereas RF-MAP-00 focuses on understanding why inheritance success changes. For detailed processing and special cases, see the individual chapters and RF-MAP-01.
